*This study was carried out in order to investigate the spatial variation of algal toxin (microcystin) concentrations along the shoreline of Lake Victoria. A total of 16 nearshore stations differing in connectivity to the main lake basin were categorized as either closed bays (ratio of bay area to bay opening <1) or open bays (ratio ≥1) and sampled during November and December 2009. Water samples were analyzed for total phosphorus, chlorophyll a, phytoplankton community composition and concentrations of microcystin. Open and closed bays were significantly different for phytoplankton abundance and composition: Average phytoplankton biovolume was higher for closed bays ( $45 \text{ mm}^3 \text{ l}^{-1} \pm 11 \text{ SE}$ ) than open bays ( $5 \pm 2 \text{ mm}^3 \text{ l}^{-1}$ ). Cyanobacterial biovolume (mainly *Microcystis* spp., *Anabaena* spp. and *Planktolyngbya* spp.) was also significantly higher in closed bays ( $82 \pm 9\%$  of total biovolume) than in open bays ( $44 \pm 5\%$ ). In contrast, diatom biovolume was lower in closed bays ( $7 \pm 1\%$ ) than in open bays ( $36 \pm 6\%$ ). Microcystins were found only among sites from closed bays and concentrations ranged from 0.4 to  $13 \mu\text{g l}^{-1}$  Microcystin-LR equivalent and coincided with high abundance of *Microcystis* spp. It is concluded that the level of water exchange from individual bays to the main basin is an important factor influencing eutrophication and microcystin production in nearshore habitats of Lake Victoria.*

**Keywords:** bay morphometry, eutrophication, *Microcystis*, *Anabaena*

---

## Introduction

During the last four decades, Lake Victoria has faced eutrophication, resulting in a general increase of bloom-forming and potentially toxin-producing cyanobacteria throughout the year (Ochumba and Kibaara, 1989; Hecky, 1993; Lung'aiya et al., 2000; Kling et al., 2001; Mbonde et al., 2004;

Ngupula et al., 2011). High levels of total phosphorus ( $>100 \mu\text{g l}^{-1}$ ) have been recorded in nearshore areas (Sekadende et al., 2005; Ngupula et al., 2012; Sitoki et al., 2013). The resulting increase in algal biomass has caused fish kills, deoxygenation of deeper waters in the lake (Ochumba, 1990) and has reduced the quality of drinking water for human consumption. Despite an

overall eutrophic state, spatial variation in phytoplankton species composition and abundance exist (Haande et al., 2011; Ngupula et al., 2011). Several studies have suggested that spatial variation in physicochemical conditions and phytoplankton density in bays of Lake Victoria is due to water exchange with the main basin, driven by surface seiches and wind activity (Haande, 2008; Okely et al., 2010; Haande et al., 2011). Other factors that can influence the variation of nearshore phytoplankton include river inflow, direct discharge of wastewater, deforestation and agricultural activities, among others (Huisman et al., 2005).

During the dry season (May–September), the Tanzanian shoreline of the lake experiences the strong seasonal South-Eastern winds (Akiyama et al., 1977), which cause upwelling of colder water from the hypolimnion and which are important in embayment dilutions (Sekadende et al., 2005). At the shore, waves induced by seiches may cause water movement in and out of shallow bays (Haande et al., 2011). Haande (2008) obtained data on the daily variation in water levels at Murchison Bay that were used to calculate water volume entering the bay. By comparing the concentrations of both lake and bay waters it was possible to calculate a dilution factor. This horizontal mixing of embayment waters with the main lake has the potential to reduce the growth of toxigenic cyanobacteria such as *Microcystis* or *Anabaena*.

In Lake Victoria, occurrence of toxins produced by cyanobacteria, particularly microcystin (MC), has been documented from Kenyan and Ugandan waters (Krienitz et al., 2002; Semyalo et al., 2010; Okello et al., 2010; Sitoki et al., 2012). At the Tanzanian side of the lake, only Sekadende et al. (2005) have reported occurrence of MC in Mwanza Gulf. MC is a hepatotoxic cyclic peptide that was repeatedly involved in toxic outbreaks of livestock and humans (Chorus and Bartram, 1999). Besides its acute toxicity it has been considered to be carcinogenic under chronic exposure conditions at the sublethal level (Svircev et al., 2009).

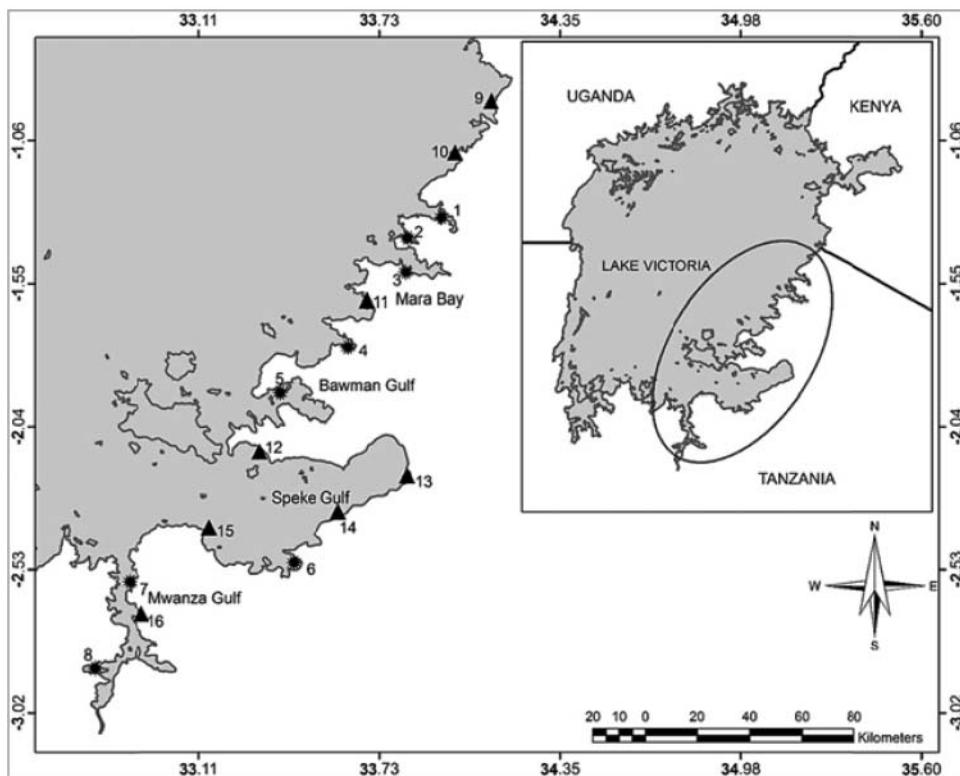

In order to understand the spatial variation in phytoplankton and MC concentration in the near-shore waters of Lake Victoria, 16 study sites located along the Tanzanian shoreline were categorized as closed and open bays (see below and Figure 1) and sampled during November and December 2009. During this time maxima in water stratification and cyanobacteria biovolume have been observed in Mwanza Gulf (Akiyama et al.,

1977) and more recently, in Nyanza Gulf (Sitoki et al., 2012). Some and Omurwa (1994) estimated through interviews that in the Lake Victoria region, 4% of all households in the Kisumu district use lake water for drinking purposes. Taking into account the local population density (National Bureau of Statistics, 2013) along the study area it can be estimated that 360,000 people depend on the lake water for their domestic use. Since these near-shore embayments experience similar climatic conditions, similar anthropogenic activities and similar eutrophication, spatial variation of phytoplankton is possibly a function of water exchange through the above indicated physical processes. It was hypothesized that the reduced exchange of closed bays with the main basin of Lake Victoria relative to open bays leads to increased biovolume of phytoplankton possibly resulting in MC occurrence.

## Materials and methods

### Study sites

The study sites comprised 16 shoreline stations with water depths below 10 m (Figure 1) that were sampled in November and December, 2009. All sites had human population density between 10,000 and 47,000 except of sites no. 1, 5 and 12 (<10,000). Sites 5, 8, 11 and 12 were located in remote areas with less industrial but moderate agricultural activities. Depending on the width of the channel opening to the main basin the sampling stations were divided into bays that showed a large surface area and narrow opening (referred to as closed bays) and consequently were considered to have a more limited water exchange to the main lake (1. Mori Bay, 2. Mugubya Bay, 3. Mara Bay, 4. Suguti Bay, 5. Bawman Gulf, 6. Magu Bay, 7. Nyegezi, 8., Chole Bay), and those that showed a smaller surface area and a more wide opening (open bays), which were considered to have significant water exchange with the main lake (9. Kirongwe Bay, 10. Shirati Bay, 11. Kiamba, 12. Bulamba, 13. Lamadi, 14. Nyamikomoma, 15. Nassa Bay, 16. Luchelele Bay). By this working definition, a closed bay had a ratio of bay surface area to bay opening below one. The closed and open bays showed a significant difference in their width of bay opening ( $p = 0.003$ ), their areas ( $p = 0.028$ ), and their ratios of area to openings ( $p < 0.001$ ), (Appendix 1, available in the online supplementary information).

**Figure 1.** Map of Lake Victoria (Southern part) showing the sampling sites on its Eastern side near the shore. Numbers 1–8 (★) are closed bays and 9–16 (▲) are open bays. Inset shows Lake Victoria and national borderlines.

## Sampling

At each station, depth-integrated water samples (from surface to the bottom) were taken using a van Dorn sampler for the quantification of total phosphorus (TP), phytoplankton abundance and biovolume, and MC analysis. From this sample, 50 ml aliquots were fixed with Lugol's solution for quantitative phytoplankton analysis. In addition, a phytoplankton net (30  $\mu\text{m}$  mesh size) was used to collect phytoplankton for qualitative analysis of phytoplankton and MC analysis. On-site measurements of water transparency (using Secchi disk), conductivity, temperature and pH were performed at the water surface using a multiprobe (HQ40d18, HACH Co.).

## Chemical analysis

Chlorophyll *a* was extracted according to ISO (1992) using hot (78°C) ethanol. TP was hydrolysed by a potassium persulphate digestion and

subsequently the total phosphate concentration was analyzed by the ammonium molybdate method (Wetzel and Likens, 2000). MCs were extracted in aqueous methanol according to Fastner et al. (1998) and analyzed using high performance liquid chromatography with diode array detection as described (Lawton et al., 1994). All peaks identified as putative MCs were collected manually for confirmation that was done using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) by Anagnostec GmbH (Potsdam Golm, Germany) as described by Kurmayer et al. (2004).

## Phytoplankton species analysis

Identification and counting of phytoplankton species were done under an inverted microscope (400  $\times$  magnification) according to Utermöhl (1958). Phytoplankton species were differentiated by morphological criteria using standard morphological keys (Komárek and Anagnostidis, 2007;

Ettl et al., 1999) and according to earlier descriptions (Talling, 1987; Komárek and Kling, 1991). Typically, species were counted as individual cells, except the cyanobacterial genera *Planktolyngbya* and *Romeria* which were counted as filaments. Calculations of phytoplankton abundance and biovolume were done according to Wetzel and Likens (2000). Sample data were compared between closed and open bays using a non-parametric rank sum test (Mann-Whitney U test). If the assumption of normal distribution was met, the Student's t-test was used. For all tests Sigma Plot 10.0 software was used.

## Results

### Difference in physicochemical parameters between closed and open bays

Overall, the differences in depth and in physicochemical parameters between the two sample categories were rather minor. Only water temperature and conductivity showed a slight, albeit significant, increase among samples from closed bays when compared with open bay samples (Table 1). There was a positive correlation between conductivity and chlorophyll *a* ( $R = 0.59$ ,  $P = 0.016$ ) and a significant positive relationship was observed between temperature and phytoplankton biovolume both within the closed bay samples ( $R = 0.78$ ,  $p = 0.02$ ) and within all samples combined ( $R = 0.75$ ,  $p < 0.001$ ).

### Difference in phytoplankton abundance and species composition between closed and open bays

In total 88 species were observed (77 in closed bays and 67 in open bays), constituting six classes, i.e. the Bacillariophyceae (23 taxa), Chlorophyceae (29), Cryptophyceae (1), Cyanobacteria (29), Dinophyceae (2), and Euglenophyceae (4). The Shannon diversity index indicated higher phytoplankton species diversity and equitability (evenness) in open bays ( $H' = 1.05$ ,  $E_H = 0.60$ ) than in closed bays ( $H' = 0.71$ ,  $E_H = 0.38$ ). A few species (20 taxa) constituted more than 1% of total phytoplankton biovolume while 15 taxa constituted more than 5%.

Although TP concentrations were similar in closed and open bays, the differences in chlorophyll *a*, total phytoplankton abundance and biovolume between the two sample sets were pronounced:  $3.4 \times 10^8 \pm 6.1 \times 10^7$  ind.  $l^{-1}$  and  $45 \pm 11$   $mm^3 l^{-1}$  in closed bays vs.  $4.1 \times 10^7 \pm 0.3 \times 10^6$  ind.  $l^{-1}$  and  $5.4 \pm 1.5$   $mm^3 l^{-1}$  in open bays (Figure 2a), (Table 1,  $p = 0.003$ ). On average, the phytoplankton biovolume recorded from closed bays was eight times higher when compared with biovolume recorded from open bays. Cyanobacteria were abundant in both closed and open bays, however, the proportion of cyanobacterial biovolume was significantly higher in closed bays ( $82 \pm 9\%$  of total biovolume) when compared with open bays ( $44 \pm 5\%$ ), ( $p = 0.007$ ). In contrast, the proportion of diatoms in total biovolume was lower in closed bays ( $6 \pm 1.4\%$ ) than in open bays ( $36 \pm 6\%$ ), ( $p < 0.001$ ). Among the cyanobacteria, *Anabaena* spp. (closed:  $31 \pm 11\%$ ; open:  $7.2 \pm 4\%$ ), *Planktolyngbya* spp. (closed:  $19 \pm 9\%$ , open:  $6 \pm 2\%$ ) and *Microcystis* spp. (closed:  $29 \pm 11\%$ ; open:  $22 \pm 7\%$ ) dominated. Within diatoms *Nitzschia* spp. (closed:  $2 \pm 0.5\%$ ; open:  $21 \pm 4\%$ ) and *Cyclotella* sp. (closed:  $2.6 \pm 0.7$ ; open:  $8.1 \pm 2.6\%$ ) dominated. Taking all data together, both the biovolume of cyanobacteria ( $R = 0.73$ ,  $p = 0.001$ ) and diatoms ( $R = 0.58$ ,  $p = 0.02$ ) were found positively related to water temperature.

### Difference in microcystin occurrence between closed and open bays

MCs were detected at five stations all being closed bays: No. 1, 2, 3, 4, 7. The MC structural variants found in different stations were identified as MC-LR (protonated mass 995.5), MC-RR (1038.4), MC-YR (1045.2), MC-AR (953.2) and di-desmethyl-MC-RR (1010.7) by the respective masses as determined by MALDI-TOF MS. The MC concentrations ranged from 0.4 to  $13 \mu g l^{-1}$  MC-LR equiv (the highest concentration occurred among samples from No. 4, Suguti). Stations No. 3, 4, 7 had high abundance of *Microcystis* spp. ( $\geq 3.03 \times 10^8$  cells  $l^{-1}$ ) and also showed MC occurrence. At some stations (No. 6, 9, 12) relatively high *Microcystis* cell numbers ( $6.8 \times 10^7 - 1.8 \times 10^8$  cells  $l^{-1}$ ) did not result in MC production. However, since *Anabaena* spp. co-occurred with *Microcystis* spp. (except at

station 4 in November) the MC producer could not be identified by correlation analysis.

## Discussion

The null hypothesis of this study was that phytoplankton abundance/biovolume was rather evenly distributed across the different stations in the lake. However, substantial differences between closed and open bays were observed. The much higher dominance of cyanobacteria in closed bays relative to open bays suggests that closed bays provided a more suitable habitat for cyanobacteria, such as *Anabaena* or *Microcystis*. In addition to reduced water exchange, many of the closed bays were surrounded by hills that can protect the bays from winds resulting in a further

reduction of water mixing. Large colony-forming cyanobacteria generally have lower growth rates when compared with diatoms and are sensitive to flushing (Reynolds et al., 2002). During calm conditions buoyant cyanobacteria like *Anabaena* and *Microcystis* accumulate on the water surface allowing for efficient light harvesting. The continued access to light through the formation of surface scums is thought to be one of the main factors contributing to the competitive success of those cyanobacteria when compared with non-buoyant phytoplankton.

In contrast, diatoms flourish under turbulent conditions reducing sinking losses to a minimum. Diatoms are also most efficient in light harvesting (Reynolds et al., 2002) which enables them to use lowest irradiances under more turbulent conditions. Particularly in the open bays wind might be

**Figure 2.** Comparison of phytoplankton biovolumes ( $\pm$ SE) of the main phytoplankton classes (a) and dominant taxa (b) between closed and open bays. Only taxa contributing  $>5\%$  to total biovolume are shown.

able to increase the mixing further in addition to the mixing caused by the horizontal water exchange with the main basin.

Both water temperature and conductivity increased among samples from closed bays. The increase in conductivity may indicate a reduced water exchange with the main basin as observed previously in the course of a sample gradient through the Nyanza Gulf (Sitoki et al., 2012). The higher temperature among closed bays may be related to the more sheltered location of these waterbodies. It is generally accepted that the optimal temperature for cyanobacterial growth often is  $25^{\circ}\text{C}$  or higher, for example, *Microcystis* strains have been shown to flourish at  $>25^{\circ}\text{C}$  (Robarts and Zohary, 1987). In this study the variation range in temperature ( $24.9\text{--}32.3^{\circ}\text{C}$ ) exceeded the variation in temperature that was observed across transects in Lake Victoria earlier (Talling, 1966). However, more data are needed to verify this near-shore variation in water temperature and its potential consequences on phytoplankton growth.

During the study period, water samples of closed bay stations of Lake Victoria (Tanzania) had detectable levels of MCs. According to earlier studies the major MC producers in Lake Victoria are *Microcystis* and *Anabaena* species (Krienitz et al., 2002; Okello et al., 2010; Semyalo et al., 2010). Okello et al. (2010) used PCR and restriction fragment length polymorphism to identify the MC producers in various freshwater lakes including Lake Victoria and found only *Microcystis* to contain the genes of the MC biosynthesis gene cluster. Nevertheless,

correlations between *Microcystis*/*Anabaena* cell numbers and MC concentrations have been frequently observed.

In this study, the abundance of *Microcystis* was not always associated with the detection of MC. In general, MC is produced when growth conditions are favorable for the cyanobacteria (Orr and Jones, 1998). Such growth conditions directly affect cyanobacteria growth, but indirectly affect MC concentrations. Environmental factors related to cellular growth and bloom formation and MC net production included high temperatures that are possibly favored by the more sheltered location of the closed bays. For example, high temperature ( $30.3^{\circ}\text{C}$ ), high MC concentrations and high *Microcystis* biovolume ( $10\text{ mm}^3\text{ l}^{-1}$ ) were recorded at Suguti Bay (No. 4) in December. Likewise, Mori Bay (no. 1) in November had the highest biovolume of *Microcystis* ( $61\text{ mm}^3\text{ l}^{-1}$ ) at  $26.9^{\circ}\text{C}$  resulting in relatively high concentrations of MCs.

The five sites in closed bays that showed MCs are located near towns (like Musoma and Mwanza, Figure 1) and untreated wastewater from the towns and agricultural activities into the lake is discharged via rivers like Mara River and Mori River. Occurrences of MCs in these areas can be a potential threat to people and their livestock health as majority of them use the near shore water for drinking before any treatment. Since these MC contaminated sites like Suguti, Mori Bay and Mara Bay are located near towns that continue to discharge nutrients into the lake, the problems of MCs may be more serious with increasing eutrophication in the near future.

When comparing the results of this study to those reported from the Kenyan and Ugandan areas (Sitoki et al., 2012; Okello et al., 2010) that have been obtained using the same system in the same laboratory (Kurmayer et al., 2004), there is some indication that toxin levels recorded in Tanzania were generally lower. Sekadende et al. (2005) also reported low MC concentrations in Mwanza Gulf (Tanzania). The higher concentrations of MCs from other parts of the lake such as Nyanza Gulf in Kenya may be explained by the characteristic morphometry of these inshore waters. Nyanza Gulf is only connected to the main basin by a narrow channel, and maximum MC concentrations  $>100 \mu\text{g MC l}^{-1}$  have been found (Sitoki et al., 2012). In general the intensity of human activities (industrialization) and hence nutrient loading gradually declines along the shore of Lake Victoria from the north to the south. Eutrophication and closed morphometry of the bays in the northern part of Lake Victoria may result in even higher growth of MC-producing colony-forming cyanobacteria such as *Microcystis* and *Anabaena* than described in this study.

## Conclusions and recommendations

Spatial variation in phytoplankton biovolume and MC concentration nearshore in Lake Victoria depend on morphometry and connectivity to the main basin rather than eutrophication alone. During this survey, human activities were frequently observed nearshore or directly in the water. The WHO drinking water guideline recommends less than  $1.0 \mu\text{g MC-LR equivalents l}^{-1}$  and  $0.2 \text{ mm}^3 \text{ l}^{-1}$  biovolume or  $1 \mu\text{g l}^{-1}$  chlorophyll *a* (Chorus and Bartram, 1999; WHO, 2006) for safe water use. Since this threshold was exceeded, the nearshore water of MC-positive sites of Lake Victoria (Tanzania) is not recommended to be used as drinking water without treatment.

Since eutrophication in the lake is still ongoing, the installation of wastewater treatment plants to reduce eutrophication particularly at those closed bay sites showing MC occurrence is highly recommended. Such wastewater treatment systems may include also the extension of wetlands along the shoreline. The effort to construct wastewater treatment systems should go hand in hand with reducing direct human waste disposal and poor agricultural practices. Regular monitoring of

phytoplankton abundance and phytoplankton composition along the shoreline by remote techniques or using multiparameter probes is highly recommended to identify all problematic sites along the Tanzanian shoreline.

## Acknowledgements

We are grateful to Gerold Winkler and Regina Brandstätter for their continuous assistance. Two anonymous reviewers provided comments that substantially improved the current manuscript. We are thankful to Tanzania Fisheries Research Institute for their cooperation during sample collection. We are indebted to Eugen Rott (Institute for Botany, University of Innsbruck, Austria) for assisting in identification of various phytoplankton species and Dr. I. Kimirei (TAFIRI-Kigoma) and Mr. C. Mashafi (TAFIRI Mwanza) for their valuable assistance during figure constructions.

## Funding

We are grateful to the Netherlands Fellowship Programme for funding this research work and the International Postgraduate Course of Limnology (IPGL) administered by the Austrian Academy of Sciences for financial support. The data analysis was financially supported by the Austrian Science Fund (P24070). This study is a contribution to the EU network “European Cooperation in Science and Technology” (COST) Action ES1105 ‘CYANOCOST’ (<http://cyanocost.com>).
